Abstract: Single-crystal neutron diffraction, inelastic neutron scattering, and density functional calculations provide experimental and theoretical analyses of the nature of the osmium-bound, “elongated” dihydrogen ligands in [Cp*OsH₄(L)][BF₄] complexes (L = PPh₃, AsPh₃, or PCy₃). The PPh₃ and AsPh₃ complexes clearly contain one dihydrogen ligand and two terminal hydrides; the H₂ ligand is trans to the Lewis base, and the H–H vector connecting the central two hydrogen atoms lies parallel to the Ct–Os–L plane (Ct = centroid of Cp* ring). In contrast, in the PCy₃ complex the H–H vector is perpendicular to the Ct–Os–L plane. Not only the orientation of the central two hydrogen atoms but also the H–H bond length between them depends significantly on the nature of L: the H–H distance determined from neutron diffraction is 1.01(1) and 1.08(1) Å for L = PPh₃ and AsPh₃, respectively, but 1.31(3) Å for L = PCy₃.

Density functional calculations show that there is a delicate balance of electronic and steric influences created by the L ligand that change the molecular geometry (steric interactions between the Cp* and L groups most importantly change the Ct–Os–L angle), changing the relative energy of the Os 5d orbitals, which in turn govern the H–H distance, preferred H–H orientation, and rotational dynamics of the elongated dihydrogen ligand. The geometry of the dihydrogen ligand is further tuned by interactions with the BF₄⁻ counterion. The rotational barrier of the bound H₂ ligand in [Cp*OsH₄(PPh₃)]⁺, determined experimentally (3.1 kcal mol⁻¹) from inelastic neutron scattering experiments, is in reasonable agreement with the B3LYP calculated H₂ rotational barrier (2.5 kcal mol⁻¹).

Introduction

Since their discovery, molecular dihydrogen complexes have generated considerable interest because they give a direct view of the intermediate (or transition state) that lies along the reaction coordinate for the oxidative addition of dihydrogen to transition-metal centers (Scheme 1). The H⋯H bond distance is often used as a measure of the extent to which the H₂ ligand has been activated. Distances less than 0.90 Å are typical for “normal” dihydrogen complexes, whereas distances longer than 1.50 Å are characteristic of classical dihydride complexes. A few dihydrogen complexes, however, constitute an intermediate situation with “elongated” H⋯H bonds of approximately 1.0–1.4 Å. In 1999, we reported the synthesis of two osmium dihydrogen complexes, [Cp*OsH₂(PPh₃)][BF₄] (1) and [Cp*OsH₂(AsPh₃)][BF₄] (2), where Cp* is η⁵-C₅Me₅. A preliminary single-crystal neutron diffraction study of 1 revealed that two of the hydride ligands (those trans to the Lewis base, L) form an “elongated” dihydrogen ligand. We now describe full details of the structures of these two complexes, along with that of the tri(cyclohexyl)-phosphine analogue [Cp*OsH₂(PCy₃)][BF₄] (3). Interestingly, the H₂ ligand in the latter molecule is oriented differently than those in complexes 1 and 2; whereas the H₂ ligand vector lies...
parallel to the $\text{Ct} \cdots \text{Os} \cdots \text{L}$ plane for $L = \text{PPh}_3$ and $\text{AsPh}_3$, it lies perpendicular to the $\text{Ct} \cdots \text{Os} \cdots \text{L}$ plane for $L = \text{PCy}_3$. In addition, the $\text{H}^\cdots \text{H}$ distance (determined from neutron diffraction) also depends on the nature of $L$, being $1.01(1)$ and $1.08(1)$ Å for $L = \text{PPh}_3$ and $\text{AsPh}_3$, respectively, but $1.31(3)$ Å for $L = \text{PCy}_3$. These structural differences are provocative because they illustrate that the geometry of a molecular dihydrogen ligand can exhibit an unusual sensitivity to the nature of the ancillary ligands. As such, the exact steric and electronic reasons for the differences are important to elucidate.

The current study combines experimental and theoretical analyses of the electronic and steric influence of these substituted phosphine and arsine ligands on the $\text{H}^\cdots \text{H}$ distance, preferred orientation, and rotational dynamics of the “elongated” dihydrogen ligands in $[\text{Cp}^\star \text{OsH}_4(L)]^+$ (where $L = \text{PPh}_3$, $\text{AsPh}_3$, and $\text{PCy}_3$; compounds 1, 2, and 3, respectively). In particular, this work reports (1) single-crystal neutron diffraction studies of 1–3, (2) the inelastic neutron scattering vibrational spectra of the protio and tetradeuterio isotopologues of the $\text{PPh}_3$ complex 1, and (3) theoretical calculations on both observed and unobserved isomers of $[\text{Cp}^\star \text{OsH}_4(\text{PPh}_3)]^+$ and $[\text{Cp}^\star \text{OsH}_4(\text{PCy}_3)]^+$.

**Experimental and Theoretical Methods**

**Syntheses.** The three compounds $[\text{Cp}^\star \text{OsH}_4(L)][\text{BF}_4]$ , where $L = \text{PPh}_3$, $\text{AsPh}_3$, or $\text{PCy}_3$, were prepared as described previously. The tetradeuterio isotopologue $[\text{Cp}^\star \text{OsD}_4(\text{PPh}_3)][\text{BF}_4]$ was made from the appropriately deuterated starting materials.

**Neutron Diffraction Data Collection and Analysis.** Time-of-flight neutron diffraction data were obtained at the Intense Pulsed Neutron Source (IPNS) at Argonne National Laboratory on a single-crystal diffractometer equipped with a position-sensitive $^6$Li-glass scintillation detector positioned at 20 K on the FDS instrument and inverse-neutron time-of-flight spectrometer at the Lujan Center of Los Alamos National Laboratory. Approximately 1 g of each sample was sealed under a He atmosphere in Al sample containers, which were then mounted in a closed-cycle He refrigerator. The raw data were normalized to the incident neutron spectrum and corrected for the instrumental response function by means of a numerical deconvolution. Theoretical INS spectra were computed with the aid of the program CLIMAX from the frequencies and atomic vibrational amplitudes of the Gaussian98/03 calculations. The only adjustable parameters in this calculation relate to instrumental factors.

**Theoretical Calculations.** The theoretical calculations were carried out using the Gaussian98(6) and Gaussian03(7) implementations of

Results and Discussion

Single-Crystal Neutron Diffraction Studies. The inner coordination spheres of the three [Cp*OsH₄(L)]⁺ cations with L = PPh₃ (1), AsPh₃ (2), or PCy₃ (3), where Cy is cyclohexyl, were determined by single-crystal neutron diffraction (Figure 1). Crystal and structural refinement data are collected in Table 1, and selected distances and angles for the three compounds are summarized in Table 2.

The PPh₃ complex 1 and the AsPh₃ complex 2 are isomorphous (nonoclop $P2_1/c$ and nearly isostructural. In both compounds, two of the hydrogen atoms (those transoid to the Lewis base) form a molecular dihydrogen ligand, whereas the two hydrogen atoms cisoid to the Lewis base are classical hydride ligands. Thus, the overall geometry is that of a four-legged piano stool, with the four legs occupied by L, two hydride ligands, and a dihydrogen molecule. For purposes of later discussions, it should be noted that the H₂ ligand (more precisely, the H–H vector connecting these two “central” hydrogen atoms) lies essentially in the Ct–Os–L plane; the relevant torsion angles are all near zero.

The average Os–H distance to the terminal hydride atoms is 1.66(2) Å, and the average Os–H distance to the dihydrogen atoms is 1.67(2) Å. The major differences between 1 and 2 are that the Os–P distance is 0.09 Å shorter than the Os–As bond length (as expected from the relative atomic radii of P and As), and the dihydrogen H(1)–H(2) distance is 1.014(11) Å in the PPh₃ complex but 1.075(13) Å in the AsPh₃ complex. The reasons for this 0.06 Å lengthening will be discussed below.

The PCy₃ complex 3 is not isomorphous with 1 and 2, and instead crystallizes with a triclinic $P1$ habit. The most interesting feature of 3 is that the dispositions of the hydrogen atoms differ dramatically from those in 1 and 2. Although the overall geometry can still be described in terms of a four-legged piano stool, in 3 the H–H vector connecting the two central hydrogen atoms is perpendicular to the Ct–Os–L plane. Other differences are apparent: the H(1)–H(2) distance between the central hydrogen atoms has increased to 1.31(3) Å. The H(1)–H(4) and H(2)–H(3) distances are also reasonably short at 1.55(3) and 1.67(3) Å, respectively. All four hydrogen ligands are nearly planar, as shown by the H(4)–H(1)–H(2)–H(3) torsion angle of only 4.9°. In addition, in 3 the Ct–Os–L angle of 139° is about 10° larger than the related angles in 1 and 2. This difference is probably due to steric crowding between the cyclohexyl groups and the cyclopentadienyl methyl groups (this point will be discussed in detail below).

It has been shown previously that coordinated dihydrogen ligands can act as hydrogen donors in hydrogen-bonding interactions owing to their electropositive character. An examination of the crystal structures shows that the BF₄⁻ counterion forms close H–•••F contacts with the dihydrogen ligands in 1–3. Specifically, three of the H–•••F contacts in 1 and 2 are shorter than the sum of the van der Waals radii (2.67 Å), the shortest being H₂–•••F₄⁺ = 2.42 Å in 1 and 2.48 Å in 2; in contrast, in 3 the shortest H–•••F contact is 2.74 Å. The intermolecular contacts are consistent with the general trend that dihydrogen ligand atoms are more electropositive than hydride ligands.

Theoretical Results. Density functional calculations were used to optimize the gas-phase structures of the cationic osmium complexes [Cp*OsH₄(L)]⁺, where L = PPh₃ or PCy₃, and the results were compared with the solid-state neutron diffraction results. The optimized structures and relative energies of the

complexes in various low-energy structures, including unobserved isomers, are shown in Figures 2–6.

Four specific angles representing the orientations of the ligands about the osmium will be used to describe and compare the experimental and calculated structures: the \( \text{Ct-Os-L} \) angle, the \( \text{C-Ct-Os-L} \) torsion (the C chosen for this torsion angle minimizes the measured angle), the \( \text{C-Ct-Os} \) angle (this C is the same one used in the \( \text{C-Ct-Os-L} \) torsion), and the \( \text{Ct-Os-H(4)} \) angle (Scheme 2).

The most stable calculated structures agree well with the experimental structures (compare Figure 1 with Figures 2–6). For both the gas-phase cationic PPh\(_3\) and PCy\(_3\) complexes, the calculated locations for the two central hydrogen atoms in the lowest energy isomers are slightly different from those determined experimentally by neutron diffraction, but the addition of the BF\(_4^-\) counterion brings the structures into closer agreement.

**Tetrahydride vs Dihydrogen–Dihydride Gas-Phase Structures.** When a polarized double-\( \zeta \) basis set is employed for the osmium-bound hydrogen atoms (BS1), DFT calculations reveal two minima for the PPh\(_3\) complex 1 with approximately equal energies and generally similar structures (Figure 2). The more stable of these two minima (by 0.53 kcal mol\(^{-1}\)) is a classical tetrahydride (1a with an H-H distance of 1.50 Å), and the other is a nonclassical dihydrogen–dihydride (1b with an H\(_2\) distance of 1.05 Å). In both isomers, the two hydrogen atoms that are “transoid” to the L ligand lie in the Ct–Os–L plane. The experimentally observed structure for 1 corresponds very closely to the latter structure (1b); the experimental H\(_2\) distance is 1.01 Å.

Apart from the difference in the H–H distance between the two central hydrogen atoms, there is another significant structural difference between 1a and 1b. In the tetrahydride isomer 1a, the Ct–Os–L angle is 125.8°, whereas in the dihydrogen–dihydride isomer 1b, the Ct–Os–L angle is 129.8°. Significantly, in the structure determined by neutron diffraction, the Ct–Os–L angle is 129.7°. Thus, the dispositions of the hydrogen atoms (and the presence or absence of a dihydrogen ligand) appear to be correlated with small changes in the angle that the Lewis base forms with the cyclopentadienyl ring.

Replacing the polarized double-\( \zeta \) basis set on the osmium-bound hydrogen atoms (BS1) with a polarized triple-\( \zeta \) basis set (BS2) brings the two structures slightly closer in energy (structure 1a now being lower in energy by only 0.04 kcal mol\(^{-1}\)) and leaves the geometric parameters essentially unchanged: the H–H distances are 1.485 and 1.015 Å for the tetrahydride and dihydrogen–dihydride isomers, respectively. An even larger basis set, with quadruple-\( \zeta \) and polarization and diffuse functions on the osmium-bound hydrogen atoms (BS4), gives virtually identical results for the geometries (H–H of 1.461 and 1.030 Å for the tetrahydride and dihydrogen–dihydride isomers, respectively), now slightly favoring the dihydrogen–dihydride isomer by 0.17 kcal mol\(^{-1}\). (The density functional calculations pertaining to the rotation of the H\(_2\) ligand and the dihydrogen/hydride exchange dynamics in this PPh\(_3\) complex and a comparison to experiment will be described below.)

L = P or As; Ct = centroid of the cyclopentadienyl ring. a The average of Ct–Os–H(1) and Ct–Os–H(2).

Scheme 2. Structural Parameters for the Osmium Complexes

For the PCy3 complex 3, the DFT calculations reveal that there are multiple minima (Figure 3). The most stable structure (3a) is a tetrahydride in which the central H–H vector is perpendicular to the Ct–Os–L plane; this orientation differs from that seen for the PPh3 complex 1 but agrees with the experimentally determined structure of 3. The H–H distance of 1.68 Å is in the range expected for classical hydrides and is longer than the 1.31(3) Å distance measured experimentally. The next lowest energy structure (+0.72 kcal mol⁻¹) is also a tetrahydride (3f), but in this case the central H–H vector lies in the Ct–Os–L plane. The H–H distance in 3f of 1.53 Å is suggestive of a weak (at best) interaction between these two atoms.

A dihydrogen–dihydride minimum structure (3b) also exists, only 1.5 kcal mol⁻¹ above the lowest energy tetrahydride structure, in which the H–H vector is still perpendicular to the Ct–Os–L plane; the H–H–H distance is 1.10 Å. Last, yet another tetrahydride–minimum energy structure (3g) exists (+0.23 kcal mol⁻¹) that perhaps would not be observed in the solid state because of crystal packing (Figure 4). In this isomer, the phosphine ligand is almost exactly trans to the centroid of the Cp* ring (Ct–Os–L angle is 171.6°) and the four hydrogen atoms are distributed symmetrically around the osmium (thus describing a local four-fold axis). This structure is similar to that observed for the isoelectronic pentahydride complex Cp*OsH5.26

The experimentally observed structure for the PCy3 complex is closest to that of 3b: in both structures the central H–H vector is perpendicular to the Ct–Os–L plane, and the Ct–Os–L angles are almost identical. The experimental H–H–H distance of 1.31 Å is somewhat longer than the 1.10 Å distance calculated for 3b; it is possible (but we think unlikely) that the crystal studied consisted of an admixture of 3b with small amounts of 3a, which has a longer H–H–H distance.

Effect of the Ct–Os–L Angle on the Structures. The optimized structures of the various isomers of the osmium complexes [Cp*OsH4(L)]⁺ show an interesting relationship between the geometry adopted by the two central hydrogen atoms and the nature of the steric interactions between L and the Cp* ligand. In agreement with experiment, the calculated lowest energy structure of the PPh3 complex has the vector of the two central hydrogen atoms parallel to the Ct–Os–L plane, whereas in the PCy3 complex this vector is perpendicular to the Ct–Os–L plane. An overlay of the calculated structures of the PPh3 and PCy3 complexes (with osmium at the origin for both, the Os–L bonds exactly aligned, and the Ct–Os–L planes superimposed) reveals the steric influence of the PCy3 ligand (Figure 5). Significantly, the Ct–Os–L angle is 129.7° in the PPh3 complex but 139.0° in the PCy3 complex, evidently owing to steric crowding in the latter complex between the Cp* and cyclohexyl groups. As discussed below, the steric crowding and/
or the rehybridization of the metal–ligand bonding orbitals that attends this change in the Ct−Os−L angle could account for why the isomer in which the H₂ ligand is perpendicular to the Ct−Os−L plane is the lowest energy one for the PCy₃ complex.

**Effect of the Orientation of the Cyclohexyl Groups in the PCy₃ Complex.** To test the hypothesis that the large steric size of PCy₃ is responsible for the stabilization of the perpendicular orientation of the two central hydrogen atoms, the conformation of one of the cyclohexyl groups in the PCy₃ complex was altered to reduce the steric repulsions between it and the Cp* group. Specifically, the cyclohexyl substituent that is in closest contact with the Cp* ring was rotated (so that its methine hydrogen atom points toward the Cp* ring instead of away from it), and then the structure was reoptimized. This change, which causes the Ct−Os−L angle to become more acute by more than 10° (so that it is more similar to the 129.7° angle seen in the PPh₃ complex 1), leads to a reversal in the relative stability of the in-plane vs perpendicular H₂ isomers. The isomer in which the central two hydrogen atoms lie parallel to the Ct−Os−L plane becomes slightly lower in energy than the isomer in which the H−H vector is perpendicular to the Ct−Os−L plane (Figure 3): compare 3c and 3e ($\Delta E = +4.21$ and $+3.08$ kcal mol⁻¹, respectively) to 3a and 3f ($\Delta E = 0.0$ and $+0.72$ kcal mol⁻¹, respectively). Of course, both of the isomers in which the cyclohexyl group is rotated are higher in energy than those in which it is oriented as seen in the experimentally determined structure. But the results again support the contention that steric effects (or their electronic consequences) govern which structure is most stable.

**Effect of the BF₄⁻ Counterion on the Structure of the Complexes.** Gusev has recently described the sensitivity of the nature of the H₂ ligand to weak intermolecular interactions in IrH(H₂)Cl₂(PPr₃)₂, a dihydrogen, hydride species. To understand the influence of the BF₄⁻ anion on the observed structures.
of our complexes, we performed DFT geometry optimizations on the [Cp*OsH₄(PPh₃)]⁺ complex (3g) with that of the lowest energy structure (3a, which is very similar to that determined by neutron diffraction). Relative energies are ΔE in kcal mol⁻¹. The angles listed are the calculated C–Os–L angles. In the lowest energy structure, the C–Os–L angle is significantly less than 180°, whereas in the higher energy structure, the phosphine ligand is almost exactly trans to the centroid of the Cp* ring. The distances listed are the calculated H—H distances for the osmium-bound hydrogen atoms (H₀ is the hydrogen at the front right, H₁ is the hydrogen at the rear right, etc.).

Figure 4. Comparison of a seventh B3LYP/BS3 optimized structure of the [Cp*OsH₄(PCy₃)]⁺ complex (3g) with that of the lowest energy structure (3a, which is very similar to that determined by neutron diffraction). Relative energies are ΔE in kcal mol⁻¹. The angles listed are the calculated C–Os–L angles. In the lowest energy structure, the C–Os–L angle is significantly less than 180°, whereas in the higher energy structure, the phosphine ligand is almost exactly trans to the centroid of the Cp* ring. The distances listed are the calculated H—H distances for the osmium-bound hydrogen atoms (H₀ is the hydrogen at the front right, H₁ is the hydrogen at the rear right, etc.).

Figure 5. Alignment of the pruned B3LYP optimized structures of [Cp*OsH₄(PPh₃)]⁺ (blue) and [Cp*OsH₄(PCy₃)]⁺ (gray). The spheres represent the centroids of the Cp* rings.
modes can therefore be readily identified. The actual nature of the particular mode must, however, be deduced from our computational study because the description of the vibrational modes for these types of large molecules can be rather complex. Despite this complication, however, the frequencies of the modes involving the dihydrogen ligand can provide useful insights into the relative strengths of the metal–H and H···H interactions in the system.

Several bands in the spectrum of the protio compound are (nearly) absent in the deuterio analogue, namely those at 172, 205, 335, 390, and 490 cm⁻¹. In contrast, a band at 145 cm⁻¹ is more intense in the spectrum of the deuterio compound. As judged from the vibrational frequencies deduced from our computational study (see below), this latter band consists mainly of methyl torsions coupled with H–Os–H deformations, so that the decreased frequency of the D–Os–D motion shifts some of the accompanying intensity from the methyl torsion at 172 cm⁻¹ to its counterpart at 145 cm⁻¹. The shoulder at 205 cm⁻¹, which disappears upon deuteration, probably corresponds to a calculated mode at the same frequency that is mainly H–Os–H deformation. As will be discussed below, on the basis of comparisons with the frequencies in the calculated spectrum of 1, the peak in the experimental spectrum at 335 cm⁻¹ is assigned to H···H torsional motion. The 390 cm⁻¹ feature is best assigned to H–Os–H wagging motions, and the strong band in the INS spectrum at approximately 490 cm⁻¹ should correspond to calculated modes at 478 and 501 cm⁻¹ that are mainly rocking and/or wagging modes of the hydride and dihydrogen ligands. These values do not differ appreciably from those observed for other dihydrogen complexes.28,30

In Figure 7b the spectrum of the protio form is compared with calculated INS spectra (unscaled frequencies) for the two lowest energy isomers of the PPh₃ complex as determined from the DFT study: 1a (classical tetrahydride structure) and 1b (nonclassical structure with an H₂ ligand). Some of the low-frequency modes in the calculated spectrum are shifted with respect to those seen experimentally; the likely anharmonic nature of these modes may well account for some of this discrepancy. Those modes involving a significant degree of methyl torsion, on the other hand, may shift to higher frequencies.

Figure 6. (a) B3LYP/BS1 optimized structure of the [Cp*OsH₄(PPh₃)]⁺[BF₄]⁻ ion pair and (b) B3LYP/BS3 optimized structure of the [Cp*OsH₄(PCy₃)]⁺[BF₄]⁻ ion pair. The H···H distances listed are those calculated for the two central hydrogen atoms. The experimental values for the PPh₃ and the PCy₃ complexes are 1.01 and 1.31 Å for the central H···H distances, respectively.

Figure 7. (a) Inelastic neutron scattering spectra of [Cp*OsH₄(PPh₃)][BF₄] (solid line) and [Cp*OsD₄(PPh₃)][BF₄] (dashed line) collected at 20 K. (b) Comparison of the experimental INS spectrum of [Cp*OsH₄(PPh₃)][BF₄] (bottom) with the INS spectra calculated for the two low-energy structures, [Cp*OsH₄(PPh₃)][BF₄] (1a, top) and [Cp*OsH₄(PPh₃)][BF₄] (1b, middle).

cies in the bulk solid because intermolecular interactions (which are neglected in our calculations on isolated molecules) tend to raise the rotational barriers for peripheral rotors.

These discrepancies aside, both calculated spectra roughly correspond with the experimental spectrum, but the calculated spectrum for the dihydrogen–dihydride isomer 1b (which is the isomer observed crystallographically) is somewhat better match. The agreement between the calculated and experimental spectra might be improved if the calculated spectrum was generated from an admixture of the dihydrogen–dihydride isomer and the slightly higher energy tetrahydride isomer; it is possible (but has not been established) that the two forms coexist at the data collection temperature of 20 K.

The dihydrogen torsional mode is found at 401 cm\(^{-1}\) in the harmonic calculation. However, the potential well for this mode (as for all motions with low or medium height rotational barriers) should be highly anharmonic, and one can calculate its frequency in a different way: in terms of a sinusoidal double-minimum potential for planar (one-dimensional) rotation used previously\(^{31}\) for metal–dihydrogen complexes. From our calculated barrier to rotation (2.53 kcal mol\(^{-1}\), see below) and the calculated H–H distance of 1.05 Å, this model predicts that the torsional mode should occur at 288 cm\(^{-1}\), and that the corresponding ground rotational state tunnel splitting should be 0.050 cm\(^{-1}\). Deviations of the potential from one that is purely sinusoidal could raise or lower the torsional mode frequency.\(^{31}\)

The experimentally observed band that matches best with the H\(_2\) torsional frequencies calculated above is the one that appears at 335 cm\(^{-1}\). If one takes 335 cm\(^{-1}\) as the frequency of the torsional mode and uses the measured rotational constant \(B\) (for \(d(\text{HH}) = 1.01\) Å, \(B = 31.5\) cm\(^{-1}\)), a sinusoidal double-minimum potential for planar (one-dimensional) rotation provides an experimental barrier of 3.1 kcal mol\(^{-1}\), which corresponds to a ground rotational state tunnel splitting of 0.028 cm\(^{-1}\). These numbers are quite reasonable and lend support to the conclusion that the band at 335 cm\(^{-1}\), which has no counterpart in the spectrum of the deuterio complex, is due to the dihydrogen torsion.

The 3.1 kcal mol\(^{-1}\) barrier for rotation of the H\(_2\) ligand in \([\text{Cp}^{*}\text{OsH}_4(\text{PPh}_3)]^+\), as deduced from inelastic neutron scattering, compares well with the value obtained from density functional calculations. In the B3LYP/BS2 calculations (BS2 has triple-\(\zeta\) plus double polarization on the metal-ligated hydrogen atoms), the (H)\(_3\) and (H\(_2\)H)\(_2\) isomers 1a and 1b are equal in energy, but are related by a calculated rotational barrier of 2.53 kcal mol\(^{-1}\).

**Effect of Steric Factors on the Electronic and Molecular Structure.** The experimentally determined structures of the osmium complexes \([\text{Cp}^{*}\text{OsH}_4(L)]^+\), where \(L = \text{PPh}_3\) (1), AsPh\(_3\) (2), or PCy\(_3\) (3), are snapshots along the oxidative-addition pathway shown in Scheme 1. For these osmium species, when the H–H axis of the dihydrogen ligand is parallel to the Ct–Os–L plane (as in 1 and 2), the dihydrogen ligand is involved in \(\pi\)-back-bonding with a metal orbital consisting of a combination of \(d_{xy}\) and \(d_{yz}\). When the H–H axis is perpendicular to the Ct–Os–L plane (as in 3), the dihydrogen ligand is involved in \(\pi\)-back-bonding with a metal orbital consisting largely of \(d_{xy}\) character. We will now show that a change in the Ct–Os–L angle inverts the relative energies of the metal orbitals presented to the bound H\(_2\).

\[\text{Figure 8.} \text{ Orbital energies for the [Cp}^{*}\text{OsH}_4(\text{PMe}_3)]^+ \text{fragment as a function of the “relative Cp}^{*}\text{tilt angle” and Ct–Os–L angle. A tilt angle of 0° corresponds to the natural Ct–Os–L angle (125°) of the minimum-energy fully optimized structure for the [Cp}^{*}\text{OsH}_4(\text{PMe}_3)]^+ \text{complex.}\]\n
Consider the hypothetical molecule \([\text{Cp}^{*}\text{OsH}_2(\text{H}_2\text{PMe}_3)]^+\) in a \(C_2\) geometry. Scanning the Ct–Os–L angle and allowing the other geometric variables to relax (by a constrained optimization, B3LYP/BS1) causes the HOMO and the second-highest occupied molecular orbital (HOMO–1) of the \([\text{Cp}^{*}\text{OsH}_2\text{PMe}_3]\) fragment to change in relative energy (Figure 8).\(^{32}\)

For the PPh\(_3\) and AsPh\(_3\) compounds 1 and 2, in which the Ct–Os–L angle is ~129° (in Figure 8), the HOMO is the \(d_{xy}\) or \(d_{yz}\) hybrid. These orbitals project two lobes of opposite sign toward the empty coordination site, and both lobes lie in the Ct–Os–L plane. Thus, the calculations predict (in agreement with experiment) that \(\pi\)-back-bonding to the \(\sigma^*\) orbital of the \(\text{H}_2\) ligand will be maximized (and the most stable structure will be formed) if the H–H vector for the dihydrogen ligand lies parallel to the Ct–Os–L plane.

For this same Ct–Os–L angle of ~129°, the \(d_{xy}\) is the second-highest occupied molecular orbital (HOMO–1) and the HOMO/HOMO–1 energy gap is large (~10 kcal mol\(^{-1}\)). This large gap means that there will be a strong preference for the \(\text{H}_2\) ligand to lie parallel to the Ct–Os–L plane. In other words, HOMO–1, whose electrons are needed to stabilize the perpendicular \(\text{H}_2\) orientation, is too low in energy to back-bond effectively into the \(\sigma^*\) orbital of the \(\text{H}_2\) ligand, and as a result the perpendicular \(\text{H}_2\) orientation is a transition state on the potential energy surface for the L = PPh\(_3\) compound.

Decreasing the $\text{Ct} - \text{Os} - \text{L}$ angle below 129° raises the energy of the HOMO and should cause stronger back-bonding to the H$_2$ ligand. Experimentally, the $\text{Ct} - \text{Os} - \text{L}$ angle is smaller in the AsPh$_3$ complex (128.5°) than in the PPh$_3$ complex (129.7°). This result arises owing to the smaller steric size of the AsPh$_3$ ligand (the larger size of the As atom vs P places the phenyl substituents farther from the metal center, thus reducing the effective cone angle of the ligand). Thus, one might expect stronger back-bonding to the H$_2$ ligand (and a longer H$^+$$\cdots$H distance) in the AsPh$_3$ complex than in the PPh$_3$ complex. The experimental H$^+$$\cdots$H distances of 1.08(1) Å for L = AsPh$_3$ and 1.01(1) Å for L = PPh$_3$ are consistent with this hypothesis, and in contrast are not easy to explain on the basis of simple electron push–pull arguments.

Increasing the $\text{Ct} - \text{Os} - \text{L}$ angle above 129° causes the two highest occupied molecular orbitals of the [Cp*OsH$_2$(PMe$_3$)$_2$]$^{+}$ fragment to become closer in energy. For the tri(cyclohexyl)-phosphine complex [Cp*OsH$_2$(PCy)$_3$]$^{+}$, the $\text{Ct} - \text{Os} - \text{P}$ angle is ~139° (Figure 8). For this geometry, the HOMO/HOMO$^{-1}$ gap is small (~2 kcal mol$^{-1}$). This small energy gap means that both the parallel and perpendicular orientations of the H$_2$ ligand correspond to minimum-energy structures on the potential energy surface.

Further insights into the orientation of the central H$_2$ ligand in these osmium complexes is provided by a theoretical analysis of four-legged piano-stool complexes conducted some years ago by Hoffmann and co-workers. In their analysis, the $p_\pi$ acceptor ability of a coordinated carbene with orientations shown in I and II was investigated. For structure I, overlap of the $p_\pi$ orbital with the metal $d_u$ orbital is maximal at a $\text{Ct} - \text{M} - \text{C}$ angle of 135°. For structure II, overlap with the metal $d_u$ orbital is maximal at a $\text{Ct} - \text{M} - \text{C}$ angle of 90°. One conclusion to draw from this study is that (steric effects aside) the preferred orientation of the carbene acceptor orbital will change from being in the $\text{Ct} - \text{M} - \text{C}$ plane at large $\text{Ct} - \text{M} - \text{C}$ angles to being perpendicular to this plane at small $\text{Ct} - \text{M} - \text{C}$ angles.

Our experimental and theoretical investigations of complexes 1–3 are consistent with this analysis, where the H$_2$ $\sigma^*$ antibonding orbital plays the role of the empty $\pi$ acceptor orbital on the carbene ligand. As shown in Table 2, in the PPh$_3$ and AsPh$_3$ complexes 1 and 2, where the $\sigma^*$ acceptor orbital is in the $\text{Ct} - \text{Os} - \text{L}$ plane, the $\text{Ct} - \text{Os} - \text{H}_2$ angle (reckoned to the midpoint of the H$^+$$\cdots$H bond) is relatively large at ~130°. In contrast, for the PCy$_3$ complex 3, in which the $\sigma^*$ orbital lies perpendicular to the $\text{Ct} - \text{Os} - \text{L}$ plane, the $\text{Ct} - \text{Os} - \text{H}_2$ angle is smaller at ~122°.

Hoffmann and co-workers also showed that the carbene acceptor orbital overlaps more strongly with orbital II than with orbital I. As a result, for our osmium complexes there should be more back-bonding to the H$_2$ ligand in the PCy$_3$ compound (the analogue of structure II) than in the PPh$_3$ and AsPh$_3$ compounds 1 and 2 (the analogues of structure I). Because stronger back-bonding into the H$_2$ $\sigma^*$ orbital should weaken and lengthen the H$^+$$\cdots$H bond, the H$^+$$\cdots$H distance should be longer in complex 3. Experiment agrees with this conclusion: the H$^+$$\cdots$H distance is 1.31(3) Å for L = PCy$_3$ but 1.01(1) and 1.08(1) Å for L = PPh$_3$ and AsPh$_3$, respectively.

Hydrogen Exchange Mechanisms. The neutron structures, the INS results, and the DFT calculations provide some insights into the possible dihydrogen/hydride exchange mechanisms in 1–3. The INS and DFT calculations (as well as NMR studies) clearly show that rotation of the H$_2$ ligand about its Os$–$H$_2$ bond is fast in all three complexes on the NMR time scale. For all three molecules, the isomer in which the H$_2$ ligand is oriented with its H–H vector perpendicular to the $\text{Ct} - \text{Os} - \text{L}$ plane (as in the ground-state structure of 3) is almost certainly important in the process that interchanges hydrogen atoms between the H$_2$ ligand and the ‘‘wing’’ classical hydride ligands. A similar intramolecular hydrogen exchange is observed in a series of iridium dihydrogen–dihydride complexes, IrX(H$_2$)H$_2$(PR$_3$)$_2$ (for X = Cl, Br, I and R = H, Me). This system is too high in energy. In contrast, the analogous iridium complex, TpIrH$_4$, which can support the higher oxidation state, can exchange by means of the oxidative addition mechanism, because the higher oxidation state structure generated by oxidative addition is too high in energy. In contrast, the analogous iridium complex, TpIrH$_4$, which can support the higher oxidation state, can exchange by means of the oxidative addition mechanism.

Variable-temperature $^1$H NMR studies of complexes 1–3 show that the four Os$–$H hydrogen atoms are exchanging with one another: the room-temperature $^1$H NMR spectra all feature a single resonance for the four Os$–$H groups. For the PPh$_3$ and PCy$_3$ compounds 1 and 3, the resonances remain sharp down to approximately ~100 °C, at which point they begin to broaden. Even at ~140 °C, however, the resonances for 1 and 3 remain broad singlets. In contrast, the hydride resonance for the AsPh$_3$ complex 2 decoalesces by ~140 °C into two broad, equal-intensity features separated by 1.0 ppm. From this chemical shift separation and the coalescence temperature, an activation energy for the dihydrogen/hydride exchange process of ~6.0 kcal mol$^{-1}$ was calculated.
DFT calculations show that there are no low-energy structures in which the $\text{H}_2$ ligand is bound to one of the “wing” coordination sites. Therefore, such intermediates can be ruled out as being important to the exchange mechanism. Instead, hydrogen exchange most likely occurs through oxidative addition to form tetrahydride intermediates, or through transition states that directly exchange one of the $\text{H}_2$ hydrogen atoms with one of the hydrides through a concerted rotation/bond-breaking transition state. If tetrahydride intermediates are involved, one possible exchange mechanism is via the symmetric isomer (L exactly trans to Cp*) depicted in Figure 4. The $\sim6.0 \text{ kcal mol}^{-1}$ barrier for dihydrogen/hydride exchange found experimentally is certainly consistent with the energy differences found by DFT between the ground-state structure and various higher energy structures with tetrahydride character.
